PATENT APPLICATION OF
RAMESH SUNDARAM AND WEI YAO
ENTITLED
GLIDE HEADS AND METHODS
FOR MAKING GLIDE HEADS

Docket No. S01.12-0881/STL 2691.1

GLIDE HEADS AND METHODS FOR MAKING GLIDE HEADS

CROSS REFERENCE TO RELATED APPLICATIONS

This application is a divisional application
5 of U.S. Application Serial No. 09/176,352, filed
October 21, 1998 and entitled "GLIDE HEADS AND METHODS
FOR MAKING GLIDE HEADS" which claims priority to U.S.
provisional patent application serial No. 60/082,235,
entitled "Method of Manufacturing Glide Heads," filed
10 on April 16, 1998.

BACKGROUND OF THE INVENTION

The invention relates to glide heads for
evaluating the glide quality of a surface of a
rotating disc. More particularly, the invention
15 relates to glide heads with improved air bearing
surface properties and to efficient methods for making
glide heads.

Disc drives are used for storing
information, typically as magnetically encoded data,
20 and more recently as optically encoded data, on a disc
surface. Glide tests are used to check disc surfaces
for defects. In particular, glide tests are used by
computer disc manufacturers to control and assure the
quality of the disc media. Generally, all hard drive
25 discs are tested before shipment. During a glide
test, the glide head or slider flies over a disc
surface generally at a predetermined clearance from
the disc surface, known as the glide height or fly
height.

30 If contact occurs between the glide head and
a disc defect or asperity, the glide head vibrates and
deforms. The vibrations can be measured with a
piezoelectric transducer (PZT), which generates a

1 varying potential difference between the electrodes of
the PZT due to forces on the transducer.
Specifically, when the glide head interacts with a
defect on the spinning disc, simultaneously excited
5 vibrational modes of the PZT and the head result in
voltage fluctuations at corresponding frequencies. If
the magnitude of measured voltages exceed
predetermined threshold values, the disc may be
rejected. Other types of transducers can be used such
10 as thermal asperity detectors or capacitance
detectors.

As storage densities on disc recording media
become higher, fly heights of read/write heads
generally become smaller. Lower fly heights impose
15 narrower restrictions on acceptable heights of
asperities/defects on a disc surface since larger
defects would result in contact between the read/write
head and the disc. Contact between a read/write head
and a disc generally results in damage to the head
20 and/or to the disc. The glide quality of a disc
directly relates to the ability of a head to fly
adjacent the disc at a fixed distance from the disc
without colliding with a defect on the disc that
results in a deformation of the head producing
25 vibrations with a magnitude above a threshold value,
as measured with the transducer. The glide quality of
a disc is related to the disc smoothness, although
other defects also may alter glide quality.

Glide heads generally are designed to have a
30 fly height that is sensitive to the linear velocity of
the disc surface relative to the glide head. To
achieve measurements of smaller asperities on the disc
surface, the disc velocity can be decreased to

decrease the fly height of the glide head.

As the operating fly height or the glide height of the glide head decreases, it becomes necessary to tighten the tolerances on the parameters
5 that induce variability in the glide head fly height.

Parameters that add to the glide head fly height variability include the surface flatness and surface roughness of the air bearing surface of the head.

SUMMARY OF THE INVENTION

10 In a first aspect, the invention pertains to a system for detecting asperities on a disc surface, the system comprising:

a glide head, wherein the glide head has an air bearing surface with a peak-to-valley flatness less than about 1
15 μ inch;

an armature for positioning the glide head over the disc; and

a transducer mounted on the glide head, the
20 transducer detecting interactions between the glide head and the disc.

In another aspect, the invention pertains to a glide head comprising an air bearing surface having a peak-to-valley surface flatness less than about 1
25 μ inch and a transducer that produces a signal in response to contact with the glide head. Moreover, the invention pertains to a wafer having a surface contoured for the air bearing surfaces of a plurality of glide heads.

30 In addition, the invention pertains to a method of producing a glide head, the method including:

contouring a smooth and flat surface of at

least a portion of a wafer to form a
desired geometry for a plurality of air
bearing surfaces of a glide head; and
slicing the wafer to form a plurality of
glide heads each with air bearing
surfaces.

BRIEF DESCRIPTION OF THE DRAWINGS

Fig. 1 is a perspective view of a substrate
wafer with a smooth top surface contoured with
structures for the air bearing surface of a glide
head.

Fig. 2 is a perspective view of the wafer
from Fig. 1 with slicing lines appropriately
indicated.

Fig. 3 is a schematic, perspective view of
the resulting glide heads cut from the wafer of Fig.
2.

Fig. 4 is a schematic, perspective view of a
glide head with a PZT transducer mounted on a wing
extending from the glide head's top surface.

Fig. 5 is a bottom, perspective view of an
alternative embodiment of a glide head, the glide head
having a negative pressure air bearing surface.

Fig. 6 is bottom view of an asperity
detection head with a thermal asperity detector.

Fig. 7 is a flow chart outlining the process
for producing the glide heads.

Fig. 8 is a fragmentary perspective view of
a section of wafer with the top surface of wafer
contoured for the air bearing surface of glide heads
using thermal transducer mounted directly on the air
bearing surface.

Fig. 9 a schematic perspective view of an

asperity detection system.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

1005045-1201
5 Glide heads/sliders can be formed from a
substrate wafer such that an extremely smooth and flat
surface of the substrate becomes the air bearing
surface of the asperity detection head. With this
approach, much of the processing of the air bearing
surface can be performed at the wafer level. Thus,
many difficult mounting and de-mounting steps can be
10 eliminated. The resulting glide heads have more
consistently flat surfaces. The improved properties
of the glide head are suitable for performing asperity
testing under more exacting tolerances. Although
contouring of the air bearing surface may introduce
15 roughness to the surface, applying the contouring to a
very smooth surface of the wafer may result in more
consistently smooth air bearing surface.

 Suitable wafers made from aluminum
oxide/titanium carbide composites (AlTiC) are
20 available from a variety of vendors including Sumitomo
(Japan), Greenleaf (Saegertown, PA), Minnesota, Mining
and Manufacturing (Saint Paul, MN) and Kyocera
(Japan). The surfaces of 4.5 inch by 4.5 inch wafers
can have a peak-to-valley flatness of less than about
25 2 μ m. Cutting the wafer into a significant number of
glide heads can result in glide heads with
significantly reduced peak-to-valley flatness due to
the reduced surface area of the glide head relative to
the wafer. The contouring of the air-bearing surface
30 onto the smooth surface of the wafer, however, can
result in some loss of flatness. Following the
contouring of the air bearing surface upon the very
smooth and flat surface of the wafer and slicing, the

air bearing surface of a glide head can have a flatness of less than about 1 μ inches, preferably less than about 0.5 μ inches, and more preferably less than about 0.2 μ inches. Measurements of flatness of a glide head can be performed using optical measuring instruments available from Wyko Corporation, Tuscon Arizona, or from Zygo Industries, Inc., Portland Oregon.

For the standard processing of a wafer into a read/write head, suitable transducers are deposited on an extremely smooth, extremely flat surface of the substrate wafer. The wafer is then cut into individual head/slider portions. Following the slicing, a cut edge is formed into an air bearing surface using contouring (e.g., ion-milling and DLC coating) and smoothing operations (e.g., rough lap, smooth lap and crown lap). The transducers formed on the smooth surface of the wafer are positioned along an edge of the resulting read/write head.

Glide heads may not have a transducer applied on a side adjacent the air bearing surface. Therefore, for production of glide heads with improved flatness and more uniform smoothness, air bearing surfaces can be defined directly on the very smooth and very flat surface of a substrate wafer. Similarly, contact detection transducers can be deposited or mounted at the wafer level on the air bearing surface or on the surface opposite to the air bearing surface. By performing a larger number of operations at the wafer level, fewer mounting, de-mount and cleaning steps are required at the slider/glide head level.

Referring to Fig. 1, wafer 100 has an

extremely smooth and flat surface 102. Rails 104 have been placed upon surface 102. Rails 104 are located on surface 102 such that they are correctly positioned on the air bearing surface of a glide head after wafer
5 100 is cut into individual glide heads. Other contours can be positioned on wafer surface 102 to form additional features on the resulting air bearing surface of the glide heads, as desired. The slicing lines 106 are shown in Fig. 2. Slicing lines 106
10 indicate schematically the location of cuts that form glide heads from wafer 100. The resulting glide heads 108 are shown in Fig. 3. Appropriately placed features on wafer surface 102 become contours on the air bearing surfaces 110 of glide heads 108 following
15 the slicing of the wafer to form the glide heads. Alternatively, some or all of the contours on the very flat air bearing surface of glide heads 108 can be formed after glide heads 108 are cut from wafer 100. While processing advantages may be lost by performing
20 the contouring after slicing the individual glide heads, the advantage of a flatter air-bearing surface can be obtained nevertheless.

Glide heads generally also include a transducer. The transducer can be a PZT transducer, a
25 conductivity transducer, a thermal transducer, or other transducers suitable for contact based asperity detection. An enlarged view of an embodiment of a glide head 140 with a PZT transducer is shown in Fig. 4. Glide head 140 has a top surface 150 including
30 wing 152. In the embodiment shown, PZT transducer 154 is supported by wing 152. PZT transducer 154 preferably can be mounted to top surface 150 prior to slicing the wafer into individual glide heads. PZT

transducer 154 is attached to a measuring circuit 156 either before or after slicing wafer 100 into glide heads 140. Air-bearing surface 160 is located on the opposite side of the glide head from top surface 150.

5 In this embodiment, air-bearing surface 160 is contoured to have rails 162, 164 as well as to produce wing 152. Generally, this structure of the air bearing surface is produced by saw cuts of the substrate.

10 An alternative embodiment of a glide head is depicted in Fig. 5. Glide head 166 has an negative pressure air bearing surface 168. A negative pressure air bearing surface results in a glide head with a fly height that is approximately independent of the
15 relative linear velocity between the glide head and the disc surface. The contours of air bearing surface 168 include rails 170 and 172 oriented as shown relative to leading edge face 174 and trailing edge face 176. Generally, air bearing surface 168 is
20 oriented substantially parallel to the opposing surface 178.

The contours of air bearing surface 168 are characteristic of contours made by ion milling or similar processing approaches. The contours of air
25 bearing surface 168 can be modified using principles known in the art to yield an air bearing surface suitable for a glide head in which the fly height varies with the linear velocity of the glide head relative to the disc.

30 The production methods described herein are suitable particularly for the production of thermal asperity detection heads with a thermal transducer placed directly on the air bearing surface. In the

embodiment shown in Fig. 6, thermal transducer 180 is located directly on air bearing surface 182 of glide head 184. Preferably, thermal transducer 180 is located on a very smooth surface formed from smooth wafer surface 102 as shown in Fig. 1.

As shown in Fig. 6, thermal transducer 180 is located on rail 188 near rear edge 186 of glide head 184. Thermal transducer 180 is in contact with electrically conductive pads 190, 192, which provide for measurements of changes in the electrical resistance of thermal transducer 180. To improve the aerodynamic performance, steps 194, 196 are located near front edge 198 of air bearing surface 182. Thermal transducers 180 are made from material with a resistance that varies with temperature. For example, materials such as NiFe alloy used to form magnetoresistive transducers also exhibit a thermal resistance effect. Electrically conductive pads 190, 192 generally are made of conducting metal, alloy or metal compound. Electrically conductive pads 190, 192 are placed after cutting glide head 184, along the edge of glide head 184 extending approximately from air bearing surface 182 to the opposite surface.

Placement of the thermal asperity detector directly on the air bearing surface provides for more sensitive asperity detection. Furthermore, the use of multiple thermal transducers can be used to grade the severity of the defect. The production and use of thermal asperity detection heads with the thermal transducer placed on the air bearing surface are described further in commonly assigned and simultaneously filed U.S. Patent application, ___/___,___ to Sundaram et al., entitled "GLIDE HEAD

FOR THERMAL ASPERITY DETECTION," incorporated herein by reference.

Fig. 7 provides a flow chart 250 outlining an embodiment of a process for producing glide heads with very flat air bearing surfaces. The process involves obtaining a wafer 252, contouring the surface of the wafer 254, applying transducers to the wafer 256, slicing the wafer to produce glide heads 258, completing the processing of the glide heads 260, and attaching the glide heads to suspensions 262. Further details on the processes and alternative processing approaches are described next.

First, a wafer is obtained 252. While not required to obtain the advantage of a flatter air bearing surface, most or all of the preparation of the air bearing surface preferably is performed at the wafer level to increase processing efficiency. In particular, the air bearing surface preferably is contoured 254 at the wafer level. A variety of contoured profiles can be used to yield desirable aerodynamic performance of the glide head as well as to provide surfaces for the support of transducers and the like. Particular examples of contoured air bearing surfaces can be seen in Figs. 4-6.

The contouring of the wafer surface to shape the air bearing surface of the resulting glide heads can be performed with one or a combination of various saw cutting, milling and deposition techniques. Preferred milling approaches include, for example, ion milling, reactive ion milling and laser ablation. A variety of deposition techniques can be used alone or in combination including, for example, photolithography and vapor deposition.

Transducers can be applied 256 at the wafer level prior to the slicing of the individual glide heads, or the transducers can be applied to the individual glide heads following cutting of the glide
5 heads. The processing is simplified if the transducers are applied 256 at the wafer level. The transducers are selected for their ability to detect the interaction of a defect with the glide head as the glide head flies above a spinning disc.

10 Transducers applied at the wafer level are located either on the air bearing surface or on the top surface opposite the air bearing surface of the resulting glide head. For example, PZT transducers detect vibrations resulting from an interaction of the
15 glide head with a defect. PZT transducers generally are placed on the top surface of the glide head either directly over the air bearing surface or on a wing extending off the side of the glide head, as shown in Fig. 4.

20 As described above, a thermal transducer can be located directly on the air bearing surface. To form the glide heads with the thermal transducers located on the air bearing surface, a plurality of thermal transducers 300 can be applied along the
25 smooth surface 302 of wafer 304, as shown in Fig. 8. Thermal transducers 300 can be applied to smooth surface 302 using thin film deposition techniques such as photolithography and vapor deposition. Thermal transducers 300 can be made from materials that change
30 electrical resistance in response to temperature changes. Preferred materials for forming thermal transducers include, for example, nickel. After deposition of the thermal transducers, a protective

layer such as diamond-like carbon (DLC) can be applied over the surface of the wafer to form a protective layer for the eventual air bearing surface of the resulting glide heads.

5 After completing the desired processing of the wafer surfaces, the wafer is "diced" or sliced 258 along cutting alleys 306, as indicated in Fig. 8, to produce cut faces. A first cut produces a set of rows with each row suitable for processing into a plurality
10 of glide heads. A second cut along each row produces the individual glide heads with four cut faces. A small quantity of material is lost along cutting alleys 306 during the slicing process.

 Following the slicing and "dicing" process,
15 any additional processing of the glide heads is completed 260. For example, if desired, the cut faces of the glide head can be smoothed using one or more stages of lapping. Lapping can involve mechanical polishing with abrasives or other smoothing processes.

20 Electrical contacts or the like can be added along the edges of the glide head, if needed. For example, electrical contact pads such as 190 and 192 of Fig. 6 can be added along the rear edge of the glide head to provide contact with a thermal transducer on the air
25 bearing surface. Additional processing can be performed to prepare the glide head for mounting to the final assembly.

 Following preparation of the glide head, it is attached to a suspension 262. The head/suspension
30 assembly also known as HGA then can be mounted on the test stand. An embodiment of an asperity/defect detection apparatus 400 is shown in Fig. 9. Glide tester 400 includes a glide spinstand 402, an arm

assembly drive 404, a suspension glide head assembly 406 and a controller 408. Glide spinstand 402 includes a spindle motor 410 and disc 414, shown in phantom lines. Spindle motor 410 supports and spins
5 disc 414. Arm assembly drive 404 has a motorized drive 420 and an arm 422. Arm 422 has a support portion 424 that connects with motorized drive 420 and an extension portion 426 that extends over disc 414. Motorized drive 420 moves arm 422 either by lateral
10 motion or by rotational motion to alter the radial position of glide 406 along a disc 414 mounted on glide spinstand 402.

Suspension glide head assembly 406 generally includes suspension 428, gimbal 430 and glide head
15 432. Suspension 428 is connects with arm 422. Glide head 432 is connected to suspension 428 by way of gimbal 430. Suspension 428 and gimbal 430 can have a variety of designs including conventional structures.

Controller 408 is connected to arm assembly
20 drive 404 and spindle motor 410. Controller 408 correlates the position of arm 422 with the rotational speed of spindle motor 410 to maintain a desired linear speed of glide head 432 relative to the disc surface. Also, controller 408 correlates impact
25 information detected by glide head 432 with a location on disc 414.

The embodiments described above are intended to be illustrative and not limiting. Additional embodiments are within the claims below. Although the
30 present invention has been described with reference to preferred embodiments, workers skilled in the art will recognize that changes may be made in form and detail without departing from the spirit and scope of the
